World Bank Policy Research Working Paper 4166, March 2007

The Policy Research Working Paper Series disseminates the findings of work in progress to encourage the exchange of ideas about development issues. An objective of the series is to get the findings out quickly, even if the presentations are less than fully polished. The papers carry the names of the authors and should be cited accordingly. The findings, interpretations, and conclusions expressed in this paper are entirely those of the authors. They do not necessarily represent the view of the World Bank, its Executive Directors, or the countries they represent. Policy Research Working Papers are available online at <http://econ.worldbank.org>.

* We thank Bettina Aten, Brian Easton, Erwin Diewert, Peter Neary, Prasada Rao, Marshall Reinsdorf, Bart van Ark and seminar participants at Dartmouth College, the NBER, and the IARIW meeting in Cork, Ireland for helpful comments, along with Chang Hong, Edwin Stuivenwold and Gerard Ypma for exceptional research assistance. Financial support was provided by the National Science Foundation and the World Bank (research grant P094655).

Abstract

From its inception, the Penn World Tables (PWT), building on the International Comparisons Program (ICP) of the United Nations, has sought to compare the *standard of living* of individuals in different countries. That is, the term “real GDP per capita” as reported in the PWT is intended to represent the ability to purchase goods and services by a representative agent in the economy. The same is true of benchmark comparisons as published by the United Nations, Eurostat or OECD. But this expenditure side interpretation of real GDP is quite different from the uses to which benchmark ICP and PWT data are frequently applied, such as in growth regressions where “real GDP” is intended to reflect the production side of the economy.

In this paper we propose a new approach to international comparisons of real GDP measured from the output side. We modify the traditional Gary-Khamis system, which measures real GDP from the expenditure side using real domestic expenditure, to include differences in the terms of trade between countries. The analysis shows that this system has a strictly positive solution under mild assumptions. On the basis of a set of domestic final output, import, and export prices and values for 151 countries in 1996, differences between real GDP measured from the expenditure and output side can be substantial, especially for small open economies.

1. Introduction

From its inception, the Penn World Tables (PWT), building on the International Comparisons Program (ICP) of the United Nations, has sought to compare the *standard of living* of individuals in different countries. That is, the term “real GDP per capita” as reported in the PWT is intended to represent the ability to purchase goods and services by a representative agent in the economy. The same is true of benchmark comparisons as published by the United Nations, Eurostat or OECD. But this expenditure-side interpretation of real GDP is quite different from the uses to which benchmark ICP and PWT data are frequently applied, such as in the “millions” of growth regressions (Sala-i-Martin, 1997) where “real GDP” is intended to reflect the production side of the economy.¹

The goal of this paper is to carefully distinguish the production or output-side measure of real GDP, denoted $real\ GDP^o$, from the expenditure-side measure, denoted $real\ GDP^e$. Real GDP^o reflects the production possibilities of an economy, whereas real GDP^e measures real expenditures which includes an adjustment for the trade balance. The reason these concepts were not distinguished in the ICP and PWT is that these projects treat the net foreign balance in an unsatisfactory way. While there may have been some data justifications for that treatment in benchmark studies of the 1970s, this is no longer the case. The treatment of exports and imports proposed in this paper will not only remove the ambiguity presently surrounding real GDP^e and real GDP^o in the ICP and PWT, but provides a rich new international measure, namely the difference between them. Essentially, these two concepts differ by the *terms of trade* in the economy, i.e. the prices at which goods are exported and imported.

In section 2, the distinction between real GDP on the output-side and expenditure-side is set out conceptually, followed by a discussion of how they can be separately measured in time series data. In order to incorporate these concepts into the PWT, however, we need to have a *cross-country* measure of their difference. To achieve this, we propose a measure of the purchasing power parity for outputs (PPP^o) rather than expenditures (PPP^e). Currently the cornerstone of the ICP and PWT is the PPP for final expenditures (PPP^e), used to deflate nominal national income to obtain real GDP^e. If instead we want to deflate nominal GDP to

¹ There are many other applications where expenditure-side real GDP is used when output-side real GDP is really needed. Recent examples are Bernard and Jones (1996), Jones and Hall (1999) and Acemoglu and Ventura (2002).

obtain *real GDP*⁰, then we need to use *PPP*⁰, which incorporates prices for exports and imports including both final goods and intermediate inputs.

In section 3 we show how *PPP*⁰ can be computed using the Geary (1958)-Khamis (1970,1972) (GK) system, and further broken down into separate *PPP*'s for final expenditures, exports and imports. It should be emphasized that by working at the level of entire economies, rather than sectors, some of the difficulties with measuring output-based *PPP*'s are avoided. In particular, we find that while the international prices of intermediate inputs are used, the corresponding domestic prices of intermediates are not needed at all. In this sense, our use of trade data provides a *short cut* to obtain output-based deflators for the entire economy.²

In section 4, we provide an empirical application of our techniques. The data used for this illustration are from the 1996 ICP-PWT benchmark comparison, using 4-digit SITC export and import unit-values for 151 countries. With the normalization that world real *GDP*^e equals world real *GDP*⁰, we find that one-third of the countries have real *GDP*^e exceeding real *GDP*⁰, which means that they are less productive than indicated by the PWT and instead benefit from high terms of trade. Included in this group are Australia, New Zealand, Japan, North America and most countries in Europe, but also a set of developing countries that happen to benefit from high unit-values on selected export products. The remaining two-thirds of countries have real *GDP*^e below real *GDP*⁰, which means that they are more productive than indicated by the PWT but have low terms of trade. That group has lower GDP per capita on average than the former group, but still includes some wealthy countries such as Australia, Hong Kong and Norway.

When we split our sample between oil and non-oil exporters, we find that the relationship between GDP and the terms of trade differs for the two sets of countries. Generally, there is a positive relationship for non-oil exporters: countries with higher per-capita GDP also have higher terms of trade. This terms-of-trade effect is driven mainly by an increase in export price levels, as import price levels are relatively stable. In contrast, we find no significant relationship between GDP per capita and the terms of trade for our set of 25 oil exporters. This appears to be

² The International Comparisons of Output and Productivity (ICOP) project at the University of Groningen constructs real GDP by sector from the output side using the industry-of-origin approach. This requires comparison of sectoral output prices across countries (see van Ark and Timmer, 2001, for example). Sectoral real output can be aggregated to obtain real output GDP, but this has only been done for a limited number of countries so far. The short-cut proposed here, which uses international rather than domestic prices of intermediates, is much easier to implement for a larger set of countries.

due to the fact that export prices in these countries are driven by movements in the global oil market that are common to all. Conclusions and directions for further research are discussed in section 5. The most important task for future work is to correct trade unit-values for quality, after which the calculation of real GDP^e and real GDP^o can be done over multiple years and incorporated into the PWT.

2. Concepts of Real GDP

The distinction between real GDP on the output and expenditure-side can be illustrated by a simple diagram in a two-good economy, shown in Figure 1. We suppose that the production possibilities frontier shifts out due to technological change. At unchanged prices, production would increase from point A to point B. Suppose, however, that the relative price of good 1 falls due to its increased supply, so that the new prices are shown by the slope of the line P_3P_3 . Production now occurs at B' rather than B. We have drawn the case where the budget lines P_1P_1 and P_3P_3 are both tangent to an indifference curve U, at points C and D, indicating that the utility of the representative consumer is unchanged.

In the case we have illustrated, the production points A and B' lie on the same ray from the origin so that the *relative outputs* of the two goods are unchanged. This means that any index of real output would be identical, and would simply equal $OB'/OA > 1$, which is the proportional increase in both outputs. This is the increase in real GDP^o as measured on the output-side.

Now suppose we pose a different question, and ask what has happened to the welfare of the representative consumer, with indifference curve shown by U in Figure 1. An exact measure of consumer welfare, or real GDP^e measured on the expenditure-side, would be *unchanged* since the consumer has the same utility at the two prices. This occurs because there has been a fall in the price of the exportable good 1. The change in real GDP^e could be measured by the change in nominal expenditure deflated by an *exact consumer price index*, constructed with the same prices as real GDP^o but using *consumption quantities* rather than *production quantities* in the index. The difference between these is exports and imports, of course, but for production quantities we also need to include the imports and exports of all *intermediate inputs*, as well as their prices. These data are not currently used by the ICP, which restricts its attention to final goods.

This distinction between real GDP on the expenditure and output-side is recognized by the United Nations 1993 System of National Accounts (SNA). The former is called real Gross Domestic Income (GDI), while the latter is real GDP. One definition³ of real GDI is:

$$\text{Real GDI} = (\text{Nominal GDP})/(\text{Domestic absorption price index}), \quad (1)$$

as compared to,

$$\text{Real GDP} = (\text{Nominal GDP})/(\text{GDP price index}). \quad (2)$$

Nominal GDP, of course, is domestic absorption (C+I+G) adjusted for the trade balance (X–M). The “domestic absorption price index” in (1) is constructed over the components of (C+I+G). By *excluding* export and import prices from this price index, changes in the terms of trade (which affect nominal GDP) are then reflected in real GDI, as demonstrated by Diewert and Morrison (1986). An improvement in the terms of trade, for example, would cause real GDI to grow faster than real GDP. Kohli (2004) has shown that this pattern holds for Switzerland, due to its terms of trade improvement. We shall avoid the term “real GDI,” because it is suggestive of the income-approach to measuring GDP (through adding up the earnings of factors) which we do not use. Instead, we use real GDP^e to reflect the expenditure-side concept like (1). This is essentially the same as “real expenditure”, except that by using nominal GDP rather than nominal expenditures in the numerator of (1) we are adjusting for the net foreign balance.

Now we come to the key question motivating this paper: which concept does the PWT use as “real GDP” – the output-side measure real GDP^o, or the expenditure-side measure real GDP^e? It turns out that the answer is unclear: the ICP constructs real GDP^e in *benchmark years*, but then to interpolate between these years, the PWT must reconcile these changes in real GDP^e with the national accounts data reports on countries real GDP growth. Since national accounts real GDP growth is closer to real GDP^o, which is being compared to benchmark estimates of real GDP^e, the distinction between these becomes lost in the reconciliation.⁴ In other words, the

³ See <http://unstats.un.org/unsd/sna1993/introduction.asp>, paragraph 16.154. The other definitions of real GDI depend on the deflator used for (X–M). Other than the domestic absorption price index, we might use the import price index, export price index, or an average of these, as recommended by Geary; see Neary (1997).

⁴ The process of reconciling the initial PWT estimates (in benchmark years) and the national accounts data for each country is described in Summers and Heston (1991, pp. 339-341).

differences between real GDP^e (using ICP data) and real GDP^o (using national accounts data) is eliminated, and the year-to-year growth of real GDP from the national accounts is used to impute real GDP in the PWT for all years in-between the benchmark years. The fact that the distinction between real GDP^e and GDP^o is not clearly made is a limitation of previous versions of the PWT that future revisions intend to improve upon.⁵

3. Measurement of Real GDP

Suppose there are $i = 1, \dots, M$ final goods, such as the categories of goods currently collected by the ICP, of which the first M_0 are non-traded. These final goods may also be used as intermediate inputs, and there are another $i = M+1, \dots, M+N$ goods that are exclusively intermediate inputs; for convenience we treat these all as traded internationally. To treat domestic demand, trade and production in a consistent framework, an input-output analysis must be used. In this framework the fundamental equality is between total demand and total supply of each good. For each country $j = 1, \dots, C$, denote final demand by q_{ij} , intermediate demand by z_{ij} , output by y_{ij} , exports by x_{ij} and imports by m_{ij} , for $i = 1, \dots, M+N$. We assume that all of these quantities are *nonnegative*, but many can be zero: in particular, the intermediate inputs $i = M+1, \dots, M+N$ have $q_{ij} = 0$, and the non-traded goods $i = 1, \dots, M_0$ have $x_{ij} = m_{ij} = 0$. Total demand in country j is given by $q_{ij} + x_{ij} + z_{ij}$, and total supply by $y_{ij} + m_{ij}$. Hence the equality between demand and supply is:

$$q_{ij} + x_{ij} + z_{ij} = y_{ij} + m_{ij}, i = 1, \dots, M+N. \quad (3)$$

Re-arranging terms, we obtain:

$$q_{ij} + x_{ij} - m_{ij} = y_{ij} - z_{ij}, i = 1, \dots, M+N. \quad (4)$$

where we refer to $y_{ij} - z_{ij}$ as “net output” of each good, i.e. gross output minus intermediate demand.

Multiplying by prices and summing over goods $i = 1, \dots, M+N$, nominal GDP can be measured either from the expenditure side (left-hand side of (4)) or from the production side

⁵ For example the title of the Phase III report of the ICP was *World Product and Income* (Kravis, Heston and Summers, 1982). This clearly implied a treatment of GDP converted at PPPs of countries as interchangeable with what is termed *output* and *expenditure* in this paper. Further the provision of output per worker figures in PWT, though provided because users were taking per capita real GDP as a labor productivity measure, clearly implies that

(right-hand side), where the units are the national currency. We presume that for a particular product, the prices of exports and imports can differ from domestic output and consumption. Such price differences always occur in practice, which is why we incorporate them here, without considering why the price differences arise. We distinguish the prices $p_{ij} > 0$ for domestic output and consumption, used to multiply q_{ij} , $i = 1, \dots, M+N$, from those for exports and imports, $p_{ij}^x > 0$ and $p_{ij}^m > 0$ respectively.⁶ Consistent with the System of National Accounts (SNA), the export prices are measured *net of tariffs and freight, including any subsidy to the buyer but not to the seller*, i.e. as the f.o.b. (free on board) price in the exporting country.⁷ Likewise, the import prices are measured *net of tariffs*.⁸

With these conventions for p_{ij}^m and p_{ij}^x , let $X_j = \sum_{i=M_0+1}^{M+N} p_{ij}^x x_{ij}$ and $M_j = \sum_{i=M_0+1}^{M+N} p_{ij}^m m_{ij}$ denote the value of exports and imports at tariff-free prices, so that nominal GDP measured on the expenditure side is:

$$\text{Nominal GDP}_j^e \equiv \sum_{i=1}^M p_{ij} q_{ij} + (X_j - M_j). \quad (5)$$

Using (4), we can re-write (5) as:

$$\begin{aligned} \sum_{i=1}^M p_{ij} q_{ij} + (X_j - M_j) &= \sum_{i=1}^{M+N} p_{ij} [(y_{ij} - z_{ij}) - (x_{ij} - m_{ij})] + \sum_{i=M_0+1}^{M+N} (p_{ij}^x x_{ij} - p_{ij}^m m_{ij}) \\ &= \sum_{i=1}^{M+N} p_{ij} (y_{ij} - z_{ij}) + \sum_{i=M_0+1}^{M+N} [(p_{ij} - p_{ij}^m) m_{ij} - (p_{ij} - p_{ij}^x) x_{ij}] \quad , \end{aligned} \quad (6)$$

where the first line is obtained by using $q_{ij} = (y_{ij} - z_{ij}) - (x_{ij} - m_{ij})$ for the final goods $i=1, \dots, M$, whereas the intermediates have $q_{ij} = 0$, so that $[(y_{ij} - z_{ij}) - (x_{ij} - m_{ij})] = 0$ for $i=M+1, \dots, M+N$. Then the second line follows because $x_{ij} = m_{ij} = 0$ for the non-traded goods $i=1, \dots, M_0$. We can interpret $(p_{ij} - p_{ij}^m)$ as import tariffs (subsidies if negative), and $(p_{ij} - p_{ij}^x)$ as exports subsidies (taxes if negative). So the final summation on the second line is interpreted as import revenue

the real GDP number is an output measure.

⁶ In principle we should also distinguish producer from consumer prices, which can differ due to taxes and retail margins, but do not incorporate that distinction here.

⁷ See <http://unstats.un.org/unsd/sna1993/introduction.asp>, paragraphs 6.235, 6.237 and 15.35.

⁸ The SNA recommends that transport costs also be removed from import prices, but that is not possible using the unit-values from UN data, where imports are measured c.i.f. (cost, insurance, freight).

less export subsidies. Adding this to the value of net output $\sum_{i=1}^{M+N} p_{ij}(y_{ij} - z_{ij})$ as in (6) gives us nominal GDP measured on the production or output side:

$$\text{Nominal GDP}_j^o = \sum_{i=1}^{M+N} p_{ij}(y_{ij} - z_{ij}) + \sum_{i=M_0+1}^{M+N} [(p_{ij} - p_{ij}^m)m_{ij} - (p_{ij} - p_{ij}^x)x_{ij}], \quad (7)$$

which clearly equals nominal GDP measured on the expenditure side, from (6).

The real counterpart to GDP measured on the expenditure-side in the PWT is obtained by using data for many countries, and computing average “reference price” for goods according to the Geary-Khamis (GK) system. The reference prices π_i^e for final goods and the purchasing power parities PPP_j^e for each country are obtained from the simultaneous equations:

$$\pi_i^e = \sum_{j=1}^C (p_{ij} / \text{PPP}_j^e) q_{ij} / \sum_{j=1}^C q_{ij}, \quad i = 1, \dots, M, \quad (8)$$

and,

$$\text{PPP}_j^e = \sum_{i=1}^M p_{ij} q_{ij} / \sum_{i=1}^M \pi_i^e q_{ij}, \quad j = 1, \dots, C. \quad (9)$$

In (8), the nominal prices p_{ij} of final goods are deflated by the PPP's, and then averaged across countries. The PPP's are obtained from (9), as the ratio of nominal to real final expenditure, where real expenditure is evaluated using the reference prices. The fact that $q_{ij} \geq 0$ in (8)-(9), along with $\sum_{j=1}^N q_{ij} > 0$, ensures a positive solution for π_i^e and PPP_j^e (Prasada Rao, 1971, Diewert, 1999). Then a normalization can be used to obtain a unique solution.

Subtracting from real expenditure the trade balance deflated by the PPP exchange rate, we obtain what is called real GDP in the PWT, and what we shall call real GDP_j^e :

$$\text{Real GDP}_j^e \equiv \sum_{i=1}^M \pi_i^e q_{ij} + (X_j - M_j) / \text{PPP}_j^e. \quad (10)$$

Notice that the trade balance $(X_j - M_j)$ is deflated by the PPP for domestic final goods, to evaluate real GDP_j^e on the expenditure side. In contrast to (10), suppose that we have reference prices for final goods, π_i^e , $i=1, \dots, M$ as well as for the traded exports and imports, π_i^x and π_i^m , for $i=M_0+1, \dots, M+N$. Then consider the following definition of real GDP_j^o on the output side:

$$\begin{aligned} \text{Real } GDP_j^o &= \sum_{i=1}^{M+N} \pi_i^o (y_{ij} - z_{ij}) + \sum_{i=M_0+1}^{M+N} [(\pi_i^o - \pi_i^m) m_{ij} - (\pi_i^o - \pi_i^x) x_{ij}] \\ &= \sum_{i=1}^M \pi_i^o q_{ij} + \sum_{i=M_0+1}^{M+N} (\pi_i^x x_{ij} - \pi_i^m m_{ij}), \end{aligned} \quad (11)$$

where the second line follows from (4) using $(y_{ij} - z_{ij}) = q_{ij}$ for non-traded final goods $i=1, \dots, M_0$, while the intermediate inputs have $q_{ij} = 0$ so that $(y_{ij} - z_{ij}) = (x_{ij} - m_{ij})$, $i=M_0+1, \dots, M+N$.

The first line of (11) is similar to nominal GDP measured on the production side in (6), but using reference prices in (11) rather than nominal prices. In principle, the first line of (11) relies on domestic reference prices for intermediate inputs (that is, π_i^o for $i=M_0+1, \dots, M+N$). But the second line of (11), where we re-write real GDP_j^o using the trade balance evaluated with reference prices, shows that the domestic reference prices for intermediate inputs are not needed after all! Essentially, the use of the international reference prices π_i^x and π_i^m gives us a short-cut method for evaluating real GDP_j^o on the output side.

To evaluate the reference prices used in (11), consider the augmented-GK system:

$$\pi_i^o = \sum_{j=1}^C (p_{ij} / PPP_j^o) q_{ij} \Big/ \sum_{j=1}^C q_{ij}, \quad i=1, \dots, M, \quad (12)$$

$$\pi_i^x = \sum_{j=1}^C (p_{ij}^x / PPP_j^o) x_{ij} \Big/ \sum_{j=1}^C x_{ij}, \quad i=M_0+1, \dots, M+N, \quad (13)$$

$$\pi_i^m = \sum_{j=1}^C (p_{ij}^m / PPP_j^o) m_{ij} \Big/ \sum_{j=1}^C m_{ij}, \quad i=M_0+1, \dots, M+N, \quad (14)$$

and,

$$PPP_j^o = \frac{\text{Nominal } GDP_j^o}{\sum_{i=1}^M \pi_i^o q_{ij} + \sum_{i=M_0+1}^{M+N} (\pi_i^x x_{ij} - \pi_i^m m_{ij})}, \quad j=1, \dots, C. \quad (15)$$

In (12) we construct domestic reference prices for the final goods, and in (13) and (14) we construct reference prices for exports and imports. These are used to construct purchasing-power-parity PPP_j^o in (15), which is the ratio of nominal GDP and real GDP_j^o . In order for these definitions to make sense, we assume:

Assumption 1

Quantities are non-negative, $q_{ij}, x_{ij}, m_{ij} \geq 0$, with $\sum_{i=1}^M q_{ij} > 0$, $\sum_{i=M_0+1}^{M+N} x_{ij} > 0$, $\sum_{i=M_0+1}^{M+N} m_{ij} > 0$.

Summing up, we have shown that the augmented-GK system (12)- (15) can be used to obtain a cross-country measure of the GDP price deflator on the output-side, which is PPP_j^o . We have therefore achieved our goal of demonstrating that final goods data, in conjunction with export or import data, can be used to construct real GDP_j^o on the output side. However, it remains to be shown that this system has a solution. This task is complicated by the fact that real GDP_j^o , appearing in (11) and the denominator of (15), is not guaranteed to be positive for all possible reference prices. This can be ruled out by some additional assumptions, as follows.

First, define the *budget shares* for each final, export and import goods as:

$$\theta_{ij}^v \equiv p_{ij}^v v_{ij} / \text{Nominal GDP}_j \geq 0, \quad v = q, x, m, \quad (16)$$

where $i=1, \dots, M$ for $v = q$; $i = M_0+1, \dots, M+N$ for $v = x, m$; and $j=1, \dots, C$. Notice that these budget shares are measured relative to nominal GDP. In addition, define the *market shares* for each good as:

$$\mu_{ij}^v \equiv v_{ij} / \sum_{k=1}^C v_{ik} \geq 0, \quad v = q, x, m, \quad (17)$$

where $i=1, \dots, M$ for $v = q$; and $i=M_0+1, \dots, M+N$ for $v = x, m$. The market shares are measured relative to the world quantity of final demand, exports or imports for each good. Denote the column vectors of budget and market shares by θ_j^v and μ_j^v for $v = q, x, m$ and country j . Then our second assumption is:

Assumption 2

For all countries $j, k = 1, \dots, C$, we have: $w_{jk} \equiv \theta_j^q \mu_k^q + \theta_j^x \mu_k^x - \theta_j^m \mu_k^m > 0$.

Clearly, this assumption limits the size of the import shares θ_{ij}^m and μ_{ij}^m . It is appropriate to think of w_{jk} as “weights” because it is readily shown that $\sum_{k=1}^C w_{jk} = 1$. While it is easy to construct examples where Assumption 2 is violated for some countries j and k , it is also true that for many values of the import budget and market shares, Assumption 2 will hold. Then we have:

Theorem

Under Assumptions 1 and 2, the system (12)- (15) has a strictly positive solution for

$\pi_i^o, \pi_i^x, \pi_i^m$, real GDP_j^o and PPP_j^o .

It is worth emphasizing that Assumption 2 is a sufficient condition to obtain this result, but is not necessary. In particular, we show in the Appendix that the vector of real GDP_j^o across countries is a row eigenvector of the matrix $W = [w_{ij}]$, corresponding to an eigenvalue of unity. Under Assumption 2, this is the Frobenius root of W and its corresponding eigenvector is strictly positive, so that real GDP_j^o is strictly positive along with PPP_j^o and all the reference prices, as stated in the Theorem. However, it is quite possible to obtain a strictly positive eigenvector and therefore a positive solution for real GDP_j^o even without having all the elements of W positive.⁹

By rewriting real GDP_j^o , it is possible to give a clear interpretation about the difference between it and real GDP_j^e . Notice that real GDP_j^o in (11) can be decomposed as:

$$\text{Real } GDP_j^o = \left(\frac{\sum_{i=1}^M \pi_i^o q_{ij}}{\sum_{i=1}^M p_{ij} q_{ij}} \right) \sum_{i=1}^M p_{ij} q_{ij} + \left(\frac{\sum_{i=M_0+1}^{M+N} \pi_i^x x_{ij}}{\sum_{i=M_0+1}^{M+N} p_{ij} x_{ij}} \right) X_j + \left(\frac{\sum_{i=M_0+1}^{M+N} \pi_i^m m_{ij}}{\sum_{i=M_0+1}^{M+N} p_{ij} m_{ij}} \right) M_j. \quad (18)$$

We can define the three ratios appearing in (18) as the inverse of the PPP's for final expenditure, exports and imports:

⁹ Assumption 2 did not hold over our entire sample of 152 countries, because initially we obtained some negative prices. As a result we dropped Nigeria, resulting in positive prices for all other 151 countries.

$$PPP_j^q \equiv \left(\frac{\sum_{i=1}^M p_{ij} q_{ij}}{\sum_{i=1}^M \pi_i^o q_{ij}} \right), \quad PPP_j^x \equiv \left(\frac{\sum_{i=M_0+1}^{M+N} p_{ij}^x x_{ij}}{\sum_{i=M_0+1}^{M+N} \pi_i^x x_{ij}} \right), \quad PPP_j^m \equiv \left(\frac{\sum_{i=M_0+1}^M p_{ij}^m m_{ij}}{\sum_{i=M_0+1}^M \pi_i^m m_{ij}} \right). \quad (19)$$

Comparing (10) and (18), it is immediate that the difference between real GDP_j^e and real GDP_j^o is due to the deflation of final expenditure, exports and imports:

$$\begin{aligned} & \text{Real } GDP_j^e - \text{Real } GDP_j^o \\ &= \left(\frac{PPP_j^q}{PPP_j^e} - 1 \right) \left(\frac{\sum_{i=1}^M p_{ij} q_{ij}}{PPP_j^q} \right) + \left(\frac{PPP_j^x}{PPP_j^e} - 1 \right) \left(\frac{X_j}{PPP_j^x} \right) - \left(\frac{PPP_j^m}{PPP_j^e} - 1 \right) \left(\frac{M_j}{PPP_j^m} \right). \end{aligned} \quad (20)$$

We will find in practice that PPP_j^e and PPP_j^q are very similar, since they are both computed from final expenditures, but with different reference prices. If these two deflators for final expenditure are equal, then either $PPP_j^x > PPP_j^e$ or $PPP_j^m < PPP_j^e$ is needed to have real GDP_j^e exceed real GDP_j^o , and both inequalities holding is sufficient for this. To interpret these conditions, it is useful to first convert export and import prices to U.S. dollars using the nominal exchange rate. Then having export prices above their reference level and import prices below their reference level will contribute towards real GDP_j^e exceeding real GDP_j^o . For example, proximity to markets that allow for higher export prices would work in this direction, but being distant from markets leading to high import prices would work in the opposite direction, raising PPP_j^m and tending to make real GDP_j^e less than real GDP_j^o .

We conclude this section with two warnings. First, the difference between our cross-country measure of real GDP_j^e and real GDP_j^o *does not* measure the gains from trade as compared to autarky. Instead, the difference between real GDP_j^e and real GDP_j^o is a measure of the gains from trade from having export or import prices that *differ* from their reference prices π_i^x and π_i^m . Since π_i^x and π_i^m are themselves *averages* of countries' actual export and import prices, it is impossible for all countries to be gaining (or losing) relative to these averages. What we can expect to find is that some countries – with high export prices or low import prices – will

gain in the sense that real GDP_j^e exceeds real GDP_j^o , whereas other countries – with low export prices or high import prices – will have real GDP_j^e less than real GDP_j^o .

Second, in order for export prices to influence the measurement of real GDP_j^o , countries need to produce some goods in common. To see this, consider the opposite case where all countries are fully specialized in their own goods. Then the summations used in (13) to obtain reference prices for the export goods would actually be over a *single* country, i.e. the unique country exporting that good. For convenience, suppose that each country exports just one good, and re-order goods so that $x_{ij} = 0$ for $i \neq j$ and $x_{jj} > 0$, so (13) becomes $\pi_j^x = p_{jj}^x / PPP_j^o$. It follows from (19) that $PPP_j^x = PPP_j^o$, so with complete specialization, the PPP for exports is identical to the overall output PPP. This means that export prices will not contribute to any differences between real GDP_j^e and real GDP_j^o ; only import prices matter. Countries with high import prices will still have real GDP_j^e less than real GDP_j^o , due to their poor terms of trade.¹⁰

4. Application to UN Trade Data and Penn World Tables

In this section we apply our formulas to a dataset for expenditure and trade in 1996 for a set of 151 countries. The source for the trade data in the NBER-UN dataset described in Feenstra *et al* (2005), and we use only data for those countries that also appear in the PWT.¹¹ This database contains specific product data classified at the 4-digit SITC level, from which we obtain unit-values for exports and imports. The number of unit-values on the export side ranges from 10 for Chad to 1,020 in the United States, and on the import side from 29 in Israel to 776 in Egypt.

It is well-known that trade unit-values are measured with error, and so we applied a regression-based procedure to omit outliers. The procedure was to predict import and export unit values based on tariff rates, distance to trading partners and exporter wages.¹² Unit values which were greater than five or less than one-fifth times the predicted unit value were identified and

¹⁰ However, in a two-good, two-country Ricardian model, a unique country imports each good. Say country j export good j and import good $i \neq j$. Then (14) becomes $\pi_j^m = p_{ij}^m / PPP_j^o$, for $i=1,2$, so that $PPP_j^m = PPP_j^o$ from (19). Since $PPP_j^x = PPP_j^o$ also, it follows by comparing (8)-(10) with (12)-(15) that $PPP_j^e = PPP_j^o$ and so real $GDP_j^e = real GDP_j^o$. Thus, the two concepts of real GDP do not differ in this case. We thank a referee for alerting us to explore it.

¹¹ The only country excluded is Nigeria, because it resulted in some negative reference prices.

omitted. By this method, 11% of the 50,115 observations for export unit values were excluded and 8% of the import unit values. The resulting cleaned data set had on average about 294 export and 432 import price observations per country.¹³

For measuring the expenditure price level, we used the PPP's for three categories of final goods (private consumption, government consumption and investment) provided by the latest version of the PWT, so $M = 3$.¹⁴ Denoting these aggregate prices from PWT by PPP_{ij} , we compute the “expenditure price levels” for each country, defined as:

$$PL_j^e \equiv PPP_j^e / E_j = \sum_{i=1}^3 (PPP_{ij} / E_j) q_{ij} / \sum_{i=1}^3 \pi_i^e q_{ij}, \quad (21)$$

where E_j denotes the local currency price of US\$ in each country j . Unlike the PPP's, the price levels are unit free, and indicate how the US\$ prices in each country compare to the reference prices, also in dollars. In column (1) of Tables 1 and 2, we report the expenditure price levels.

We next combine the three categories of final goods with $i = 4, \dots, N+3$ categories of export and import unit-values, and compute the extended-GK system in (12)-(15). In column (2) we report the relative output price level PL_j^o , computed as PPP_j^o / E_j . The normalization used in column (2) is identical to that in column (1), i.e. the value of real GDP_j^e or real GDP_j^o summed over all 151 countries equals the summed nominal value of GDP in US\$. The difference between the output price levels PPP_j^o and expenditure price levels PPP_j^e , and hence between real GDP measured either from the output or the expenditure side, varies highly across countries, as shown in column (9). In Table 1 we report the 51 countries with real $GDP_j^e > real\ GDP_j^o$, and in Table 2 the 100 countries with real $GDP_j^e < real\ GDP_j^o$; the sample is also divided this way for the summary statistics reported in Table 3.

¹² These regression results are available on request.

¹³ We also experimented with a looser criteria, omitting only unit values greater than 10 or less than one-tenth. In this case, the percentages omitted unit values drops to 5.4% for exports and 3.2% for imports, but the overall results are similar to those reported here.

¹⁴ An alternative to using just three categories of final goods (private consumption, government consumption and investment) is to use the benchmark ICP data for 1996, which gives 30 categories of final goods. However, that benchmark data is only available for about 50 countries (for which we also have trade data). By collapsing the 30 final goods into three aggregates, and using those PPP's from PWT, we instead obtain data on 151 countries.

Output price levels are decomposed into price levels for final goods, exports and imports:

$$PL_j^q \equiv PPP_j^q / E_j = \sum_{i=1}^3 (PPP_{ij}^q / E_j) q_{ij} / \sum_{i=1}^3 \pi_i^q q_{ij} , \quad (22)$$

$$PL_j^x \equiv PPP_j^x / E_j = \sum_{i=4}^{N+3} (p_{ij}^x / E_j) x_{ij} / \sum_{i=4}^{N+3} \pi_i^x x_{ij} , \quad (23)$$

$$PL_j^m \equiv PPP_j^m / E_j = \sum_{i=4}^{N+3} (p_{ij}^m / E_j) m_{ij} / \sum_{i=4}^{N+3} \pi_i^m m_{ij} . \quad (24)$$

These price levels are reported in columns (3), (5) and (6) in Table 1. The ratio of PL_j^x / PL_j^m is reported as the terms of trade for each country in column (4):

$$TOT_j \equiv PL_j^x / PL_j^m , \quad j = 1, \dots, C. \quad (25)$$

A number of observations can be made. First, the output price levels for final goods in column (3) are very close to the expenditure price levels in column (1), which is encouraging. It indicates that the use of a different set of reference prices for final goods does not influence the estimation of a PPP for final goods: PPP_j^q is almost equal to PPP_j^e . The choice for output prices for final goods π_i^q or expenditure prices π_i^e , where the former is influenced by exports and imports via the simultaneous system (12)- (15), but the latter is not, is inconsequential.

Second, export price levels differ greatly across countries (see column 5). The highest export price levels are found for Switzerland, Ireland, Sweden and Bermuda, while low levels are found for countries such as Bangladesh, Cambodia, Guinea Bissau, Lao and Nepal. Several factors play an important role in explaining differences in export prices. It is well known that under imperfect competition, exporters can and do charge different prices in various destination markets. Such market segmentation can arise in response to changes in nominal exchange rates, or trade policies of the importer. In addition, it is becoming recognized that countries differ systematically in their qualities and bundles of export goods (Lipsey, 1994; Schott, 2004). This would also create differences in the relative unit-value of their exports.

To give one specific example, Bermuda has the highest terms of trade, which is explained by a high price level for exports as compared to imports. Ships and boats (SITC 7932) is by far the most important export product, with exports of \$145 million in 1996, and a export unit-value

of \$2,680 per metric ton. This is higher than its reference price of \$1,910 per ton. So Bermuda's exports of ships and boats are priced higher than the world average, and this product is primarily responsible for Bermuda's high price level for exports. To the extent that the boats exported from Bermuda are of higher quality than other countries (which seems quite plausible to us), then the high price level of exports and high terms of trade is being driven by quality rather than a pure price difference with other countries. As we discuss in the conclusions, correcting the unit-values for quality is the most important direction for further research.

The third observation is that import price levels of countries, shown in column (6) of Table 1, are much closer together than export prices – the standard deviation of import price levels are less than two-thirds for exports, and less than half that for final goods, as shown in Table 3. This might be related to the fact that import baskets are much more similar across countries than export baskets. High import prices are found for countries like Japan, Korea, Switzerland and Scandinavian countries, whereas Benin, Gambia, Mexico, Niger and Sierra Leone are prominent examples of countries in which import price levels are low.

Dividing the export and import price level, we obtain the terms of trade for each country. These are especially low for countries like Cambodia, Guinea Bissau, India, Lao, Mongolia and Nepal. In these countries terms-of trade were lower than 60, indicating that their export PPPs are much lower than their import PPPs. In contrast, countries like Bermuda, Democratic Republic of Congo, Equatorial Guinea, Ireland, Malta, Niger and Switzerland benefit from high terms of trade (140 or higher). Those countries with high terms of trade also tend to have real $GDP_j^e > \text{real } GDP_j^o$, but that is not guaranteed because the value of exports and imports also enter (20).

Overall, we find that one-third of the countries (51) have real GDP_j^e exceeding real GDP_j^o , which means that they are less productive than indicated by the PWT and instead benefit from high terms of trade. Included in this group are Australia, New Zealand, Japan, North America and most countries in Europe, but also a set of developing countries that happen to benefit from high unit-values on selected export products. The most extreme case in this group is Bermuda, which has real GDP_j^e twice as high as real GDP_j^o , which is explained by its high export unit-value for sailboats. The remaining two-thirds of countries (100) have real GDP_j^e

below real GDP_j^o , which means that they are more productive than indicated by the PWT and have low terms of trade. That group has lower GDP per capita on average than the former group, but still includes some wealthy countries such as Hong Kong, for which real GDP_j^e is two-thirds that of real GDP_j^o , due to low export prices from Hong Kong.¹⁵

An alternative way to split our sample is by oil and non-oil exporters, since we expect the relationships for the two sets of countries may be different.¹⁶ In Figure 2 we plot the terms-of-trade and GDP per capita levels for the set of 126 non-oil exporting countries, together with the regression line. Generally, there is a positive relationship: countries with higher per-capita GDP also have higher terms of trade. The slope coefficient on GDP per capita is significantly positive (at the 5% level). This terms-of-trade increase is driven mainly by an increase in export price levels, as import price levels are relatively stable (see Table 3). However, GDP per capita explains only 5% of the variation in the term of trade. In contrast, we find no significant relationship for our set of 25 oil exporters (see Figure 3). This appears to be due to the fact that export prices in these countries are driven by movements in the global oil market that are common to all.

The pattern shown in Figure 2, whereby countries with higher per-capita GDP have higher terms of trade, carries over to the comparison of real GDP^e and real GDP^o . In Figure 4, a comparison of the two is given for the full set of countries, together with the 45 degree line. In column (9) of Table 1 the difference between the two is given as a percentage over real GDP_j^o . The magnitude of this difference depends on the openness of a country and its terms-of-trade. For example, although India had a particularly low terms-of-trade in 1996, the difference between real GDP_j^e and real GDP_j^o is only 4%, due to its low share of exports and imports in GDP. Alternatively, big differences can be found for small open economies such as Bermuda, Ireland, Israel, Malta and Singapore in which real GDP_j^e was at least 30% than real GDP_j^o due to advantageous terms-of-trade. Countries such as the Bahamas, Hong Kong, Moldova, Macao,

¹⁵ An number of electronic products exported from Hong Kong have lower unit-values than those exports from other countries. An example is electronic microcircuits (SITC 7764), which sell for \$1.09 from Hong Kong, but \$1.43 from Japan and \$1.74 from the U.S.

¹⁶ Oil-exporters are defined as those having export shares of mineral fuels of at least 25%. Data on mineral fuel exports is taken from the World Bank, *World Development Indicators*.

Mongolia and Norway are prominent examples of the opposite, with real GDP^e at least 19% lower than real GDP^o due to disadvantageous terms-of-trade.

5. Conclusions

In this paper, it has been shown that there is a fundamental difference between real GDP measured from the output side or from the expenditure side in international comparisons. The difference between the two concepts is in the treatment of the terms of trade. Real GDP from the expenditure side represents the ability to purchase goods and services while real GDP from the output side measures the production possibilities of the economy. It is the latter concept of real GDP which is of interest to many studies of growth and convergence in the world economy. However, available data from the Penn World Tables are based on a mix of cross-country expenditure-side measures of real GDP for benchmark years, with national growth rates of real GDP based on output-side measures.

In this paper a clear-cut distinction between the two measures is made. It is shown that real GDP^e can overstate real GDP^o by as much as 100% (for Bermuda) and understate it by as much as 33% (for Hong Kong). In these two extremes and other cases, we would want to closely examine the export unit-values before treating the estimates of real GDP_j^o as reliable. For Bermuda, its exported sailboats may well be of higher quality than the world average, which indicates that we are overstating its high terms of trade. Conversely, the low export unit-values for Hong Kong may reflect its status as an entrepôt economy, processing and shipping goods from China and elsewhere in Asia. It is impossible to avoid using these trade unit-values as measures of prices, however, since no dataset exists for comparing actual trade prices across countries. So it is essential that we should attempt to correct the unit-values for differences in quality across countries. Recent papers along these lines include: Choi, Hummels and Xiang (2006), Feenstra and Romalis (2006), Hallak (2006), Hallak and Schott (2006), Hummels and Klenow (2005), and Timmer and Richter (2006); and we can hope that enough progress will be made on these methods to allow implementation over a wide set of countries, products and years. In our view, that is the key theoretical and empirical issue that must be resolved before applying the techniques described herein to obtain separate measures of real GDP on the output side, and the expenditure side, in the Penn World Tables.

Appendix: Proof of Theorem

Denoting nominal GDP_j by G_j and real GDP_j^o by R_j^o, j = 1,...,C, we can substitute PPP_j^o =

R_j^o / G_j in (12)- (14) to obtain the reference prices,

$$\pi_i^o = \sum_{j=1}^C R_j^o \theta_{ij}^q / \sum_{j=1}^C q_{ij}, \quad i = 1, \dots, M, \quad (A1)$$

$$\pi_i^x = \sum_{j=1}^C R_j^o \theta_{ij}^x / \sum_{j=1}^C x_{ij}, \quad \pi_i^m = \sum_{j=1}^C R_j^o \theta_{ij}^m / \sum_{j=1}^C m_{ij}, \quad i = M_0 + 1, \dots, M + N, \quad (A2)$$

where we are making use of the definitions of budget shares in (16). Also using the market shares in (17), real GDP_j^o can be computed from (11) as,

$$R_k^o = \sum_{j=1}^C \sum_{i=1}^M R_j^o \theta_{ij}^q \mu_{ik}^q + \sum_{j=1}^C \sum_{i=M_0+1}^{M+N} R_j^o (\theta_{ij}^x \mu_{ik}^x - \theta_{ij}^m \mu_{ik}^m) = \sum_{j=1}^C R_j^o (\theta_j^q \mu_k^q + \theta_j^x \mu_k^x - \theta_j^m \mu_k^m). \quad (A3)$$

Define w_{jk} as the last term in parentheses in (A3), W = [w_{jk}] as the corresponding CxC matrix, and R^o as the row vector (R₁^o, ..., R_C^o). Then (A3) can be re-written as R^oW = R^o, so that the R^o is a row eigenvector of the matrix W.

It is readily checked that each row of W sums to unity. Since W is strictly positive by Assumption 2, from the Frobenius theorem it has a positive eigenvalue that lies in-between the minimum and maximum of its row sums, and the associated row or column eigenvector is strictly positive. Since the row sums are all unity, then the Frobenius eigenvalue also equals one, and R^o is the strictly positive row eigenvector corresponding to that eigenvalue. Using this in (12)-(18) we obtain strictly positive solutions for PPP_j^o and the reference prices. QED

Notes to Tables 1 and 2:

All price levels are multiplied by 100.

Columns (1) and (2) are normalized so that the real value of GDP across all countries equals the nominal value of GDP in US\$.

Columns (3) and (4) decompose the output price level taken from column (2).

Column (4) equals (5)/(6).

Columns (7) and (8) are computed according to equations (12) and (14), respectively.

Column (9) equals [(7)-(8)]/(8).
